Abstract

The complexity of the signaling network that underlies astrocyte-synapse interactions may seem discouraging when tackled from a theoretical perspective. Computational modeling is challenged by the fact that many details remain hitherto unknown and conventional approaches to describe synaptic function are unsuitable to explain experimental observations when astrocytic signaling is taken into account. Supported by experimental evidence is the possibility that astrocytes perform genuine information processing by means of their calcium signaling and are players in the physiological setting of the basal tone of synaptic transmission. Here we consider the plausibility of this scenario from a theoretical perspective, focusing on the modulation of synaptic release probability by the astrocyte and its implications on synaptic plasticity. The analysis of the signaling pathways underlying such modulation refines our notion of the tripartite synapse and has profound implications on our understanding of brain function.

Abbreviations:

Adn: adenosine; AFM: amplitude and frequency modulation; AM: amplitude AMPA: 2-amino-3-(5-methyl-3-oxo-1,2- oxazol-4-yl)propanoic acid; **AMPAR**: AMPA glutamate receptor; **ATP**: adenosine triphosphate; Ca^{2+} : calcium; CICR: Ca²⁺-induced Ca²⁺ release; D-ser: D-serine; EAAT: excitatory amino-acid transporter; ER: endoplasmic reticulum; FM: frequency modulation; GABA: yaminobutyric acid; GJC: gap junction channel Glu: glutamate; GluR: glutamate receptor; mGluRs: metabotropic GluR; GPCR: Gq protein-coupled receptor; IP-**5P**: inositol polyphosphate 5-phosphatase; **IP**₃: inositol 1,4,5-trisphosphate; **IP**₃-**3K**: IP₃ 3-kinase; IP₃R: IP₃ receptor; LTD (LTP): long-term depression (potentiation); **NMDA**: *N*-methyl-D-aspartic acid: **NMDAR**: NMDA glutamate receptor; **PLCδ** (**PLCβ**): phospholipase $C\delta$ ($C\beta$); **PPR**: paired-pulse ratio; **PR**: purinergic receptor; PSC: postsynaptic current; SIC: slow inward current; SNARE: soluble Nethylmaleimide-sensitive factor attachment protein; STDP: spike-timing – dependent plasticity; **TACE**: TNFα-converting enzyme; **TNFα**: tumor necrosis factor-α.

Introduction

The simultaneous recognition that astrocytes sense neighboring neuronal activity and release neuroactive agents (or "gliotransmitters") has been instrumental in the uncovering of the many roles played by these cells in the control of genesis, function and plasticity of synapses (Zorec et al., 2012; Santello and Volterra, 2009; Bains and Oliet, 2007; Volterra and Meldolesi, 2005; Ullian et al., 2004; Haydon, 2001). These findings initiated a conceptual revolution that leads to rethinking how brain communication works since they imply that information travels and is processed not just in the neuronal circuitry but in an expanded neuron-glial network (Giaume et al., 2010; Volterra and Meldolesi, 2005; Haydon, 2001). On the other hand the physiological need for astrocyte signaling in brain information processing and the mode(s) of action of these cells in computational tasks remain largely undefined. This is due, to a large extent, both to the lack of conclusive experimental evidence, and to a substantial lack of a theoretical framework to address modeling and characterization of the many possible astrocyte functions. This review aims at introducing such a perspective providing a framework for future modeling efforts in the field based on preliminary theoretical studies on both astrocytic calcium signaling and gliotransmitter-mediated modulations of synaptic release probability.

A theoretical framework for astrocyte-synapse interactions

Control of synaptic transmission and plasticity by astrocytes subtends a complex signaling network, which involves different biochemical pathways (Zorec et al., 2012; Volterra and Meldolesi, 2005). In general, synaptically-released neurotransmitter can spill out of the synaptic cleft and bind to metabotropic receptors found on the neighboring astrocytic processes triggering there inositol 1,4,5-trisphosphate (IP₃)-mediated Ca²⁺ signaling. This was observed at both glutamatergic, cholinergic, noradrenergic and GABAergic synapses in the hippocampus, in the thalamus and in the cortex (Navarrete et al., 2012; Halassa and Haydon, 2010; Santello and Volterra, 2009; Haydon and Carmignoto, 2006; Volterra and Meldolesi, 2005). Figure 1A summarizes a number of observations made at the level of hippocampal glutamatergic synapses (Santello and Volterra, 2009; Bains and Oliet, 2007). There, synaptic glutamate can trigger Ca²⁺ signaling in the surrounding astrocytic processes via metabotropic glutamate

receptors (mGluRs) (Panatier et al., 2011; Fiacco and McCarthy, 2004; Pasti et al., 1997). There is also evidence in the dentate gyrus that ATP, possibly synaptically-released, triggers astrocytic Ca²⁺ signaling through the activation of metabotropic purinergic P₂Y₁ receptors (Di Castro et al., 2011; Larsson et al., 2011; Santello et al., 2011; Jourdain et al., 2007). Following elevation of intracellular Ca²⁺, astrocytes can release glutamate as well as other chemical transmitters such as D-serine (D-ser) and ATP which can be converted into adenosine (Adn) in the extracellular milieu (Henneberger et al., 2010; Parpura and Zorec, 2010; Montana et al., 2006; Pascual et al., 2005; Bezzi et al., 2004). Astrocyte-released glutamate diffuses in the extrasynaptic space and may bind to glutamate receptors (GluRs), including mGluRs and NMDARs on neighboring presynaptic terminals, modulating the release of neurotransmitter (Di Castro et al., 2011; Bonansco et al., 2011; Jourdain et al., 2007; Perea and Araque, 2007; Fiacco and McCarthy, 2004). An analogous action on synaptic release could also be due to astrocytederived ATP and its derivative adenosine through presynaptic purinergic receptors (PRs), including both A_1 and A_2 receptors (Panatier et al., 2011; Halassa and Haydon, 2010; Pascual et al., 2005). On the postsynaptic side, astrocytic glutamate and D-serine may bind to extrasynaptic NR₂B-containing and postsynaptic NMDARs respectively, modulating neuronal firing and participating in the induction of long-term potentiation (Henneberger et al., 2010; Bains and Oliet, 2007; Fellin et al., 2004). Astrocytes could also release TNF α by Ca²⁺-dependent activation of TNF α -converting enzyme (TACE) (Santello and Volterra, 2012; Bezzi et al., 2001), which could strengthen excitatory synaptic transmission by promoting surface insertion of AMPA receptors (AMPARs) (Bains and Oliet, 2007; Stellwagen and Malenka, 2006; Beattie et al., 2002). This signaling route could also play a role in pathological states such as post-traumatic epilepsy (Volman et al., 2011; Balosso et al., 2009) or spinal chord injury (Ferguson et al., 2008; Stellwagen et al., 2005). On the other hand, extracellular levels of TNFα control glutamate release from astrocytes ultimately modulating the astrocytic action on presynaptic function (Santello et al., 2011; Domercq et al., 2006). This intricate signaling network is further complicated by the possibility that astrocyte Ca2+ events are triggered by additional mechanisms including the action of ATP realeased extracellularly by the astrocytes themselves or of IP₃ diffusing intracellularly from one astrocyte to another one through gap junction channels (GJCs) (Scemes and Giaume, 2006; Kang et al., 2005). At Schaffer collateral synapses, astrocytic Ca²⁺ increases could also be promoted by retrograde endocannabinoid signaling from postsynaptic terminals via activation of endocannabinoid CB₁ receptors (Navarrete and Araque, 2010; Navarrete and Araque, 2008) (omitted from Figure 1A for clarity). Moreover, the relation between astrocytic Ca²⁺ and gliotransmitter release is not simple: some of the Ca²⁺ signals that can be generated in astrocytes are apparently not able to induce gliotransmitter release or its synaptic consequences (Lovatt et al., 2012; Agulhon et al., 2010; Agulhon et al., 2008; Petravicz et al., 2008; Fiacco et al., 2007), while gliotransmitters can also be released by mechanisms that are independent of Ca²⁺ signaling (Parpura and Zorec, 2010) (not included in Figure 1A for simplicity).

Despite its apparent complexity, the ensemble of the astrocyte-synapse signaling interactions discussed above can be well captured by the modeling scheme of Figure 1B. This scheme shows the three essential components of the astrocyte-regulated synapses, also referred to as "tripartite synapses" (Haydon, 2001; Araque et al., 1999): these are the pre- (PRE) and postsynaptic (POST) terminals, and the astrocyte, i.e. an astrocytic process surrounding the synaptic elements (ASTRO) (Haydon, 2001; Araque et al., 1999). Moreover, in addition to the classical neuronal path that leads from the input presynaptic action potentials, commonly referred to as input spikes (IN), to the output postsynaptic current (OUT), further input and/or output pathways (I/O) could coexist due to the above-mentioned routes based on astrocytic Ca²⁺ signaling (Giaume et al., 2010). Focusing on the synapse-astrocyte coupling, three fundamental pathways are identified: one (A) from the synapse to the astrocyte whereby synaptically-released glutamate (or other synaptic agents) promotes Ca²⁺ signaling in the astrocyte and the other two (B and C) from the astrocyte to synaptic terminals, whereby glutamate or ATP released from the astrocyte affects synaptic function (Santello and Volterra, 2009; Volterra and Meldolesi, 2005). Additional pathways supported by other neuroactive agents such as Dserine or TNFα can also be evoked in parallel to those shown in Figure 1B but they would not alter the essence of the scheme. Moreover, although based on experimental results at excitatory synapses in the hippocampus, (Santello et al., 2011; Andersson and Hanse, 2010; Perea and Araque, 2007; Jourdain et al., 2007; Fiacco and McCarthy, 2004; Araque et al., 1998; Araque et al., 1998), the modeling scheme in Figure 1B could also hold for other reported pathways such as GABA-evoked gliotransmission at interneuron-to-pyramidal cell synapses in the hippocampus (Serrano et al., 2006; Kang et al., 1998), or glia-mediated ATP release at hippocampal synapses (Pascual et al., 2005), in the hypothalamus (Gordon et al., 2009) and in the retina (Newman, 2005; Newman, 2003), or glial modulation of neuromuscular transmission (Rousse et al., 2010; Todd et al., 2010; Robitaille, 1998) (see Table 1 for a summary of the possible signaling pathways).

Analysis of the scheme in Figure 1B reveals that astrocytes mediate two loops in the signal flow from the presynaptic to the postsynaptic terminal: a feedforward and a feedback one. The feedforward loop ends on the postsynaptic terminal and is activated when synaptic glutamate and/or ATP induces glutamate and/or D-serine release from the astrocyte to the postsynaptic element, i.e. the A-C path in Figure 1B (Santello and Volterra, 2009; Barres, 2008; Bains and Oliet, 2007). The feedback loop ends on the presynaptic terminal (the A-B path in Figure 1B) and is activated when synaptic glutamate or ATP trigger Ca²⁺-dependent release of glutamate and/or ATP from the astrocyte to the presynaptic terminal, leading to modulation of synaptic release through specific presynaptic receptors (Halassa and Haydon, 2010; Santello and Volterra, 2009). In principle the two pathways could coexist at the same synapse where they are expected to display different dynamics and respond to different preferred input stimuli. Therefore their coexistence at the same synapse could give rise to complex effects that are hard to quantify when considered altogether. Accordingly, a common approach in experiments is to characterize their effects on synaptic function by separate manipulations of pathways A, B, C (Figure 1B) using different techniques (Di Castro et al., 2011; Panatier et al., 2011; Santello et al., 2011; Marchaland et al., 2008; Jourdain et al., 2007; Montana et al., 2004). For example, the characterization of the feedback pathway on the presynaptic terminal (A–B) can be carried out by opening the feedback loop (for example by inhibiting elements of A or B) and analyzing the signaling components separately. From a theoretical point of view, this approach is put forth by at least three steps of analysis that are: (1) characterization of Ca2+ dynamics in the astrocyte as a function of different synaptic inputs (that is, pathway **A**); (2) characterization of how gliotransmitter release from the astrocyte depends on different astrocytic intracellular Ca²⁺ dynamics; and (3) characterization of the effect on synaptic release of Ca²⁺-dependent gliotransmitter release from the astrocyte (i.e. pathway **B**). These three aspects are discussed below from a modeling perspective, focusing on their possible roles in synaptic information processing.

Characteristics of astrocyte Ca²⁺ excitability and its relationship with synaptic activity

Intracellular Ca²⁺ elevations in the astrocyte are not simple on-off signals (Di Castro et al., 2011; Zonta and Carmignoto, 2002; Carmignoto, 2000). There are multiple and varied spatiotemporal patterns of Ca²⁺ elevation, which probably underlie different types of function, including generation of diverse output signals (Zorec et al., 2012; Volterra and Meldolesi, 2005; Carmignoto, 2000). Two main types of neuronal activity-dependent Ca²⁺ responses are observed in astrocytes (Scemes and Giaume, 2006; Zonta and Carmignoto, 2002; Codazzi et al., 2001; Matyash et al., 2001; Grosche et al., 1999): (1) transient Ca²⁺ increases that are confined to their distal processes (Di Castro et al., 2011; Nett et al., 2002; Pasti et al., 1997) and (2) Ca²⁺ elevations propagating along these processes as regenerative Ca²⁺ waves, often eventually reaching the cell soma (Sul et al., 2004; Pasti et al., 1997). This latter kind of event can even propagate to neighboring astrocytes, giving rise to intercellular Ca²⁺ waves (Kuga et al., 2011; Tian et al., 2005). On the other hand, intercellular Ca²⁺ propagation does not necessarily need propagation through the cell soma and has been observed across astrocytic processes or from an end foot to an end foot (Giaume et al., 2010; Mulligan and MacVicar, 2004).

The precise signaling cascades underlying the various forms of Ca²⁺ elevation are not completely understood. In general, Ca²⁺ signals in astrocytes are determined by an intricate interplay of amplification, buffering, and extrusion pathways linked to cytosolic Ca²⁺ elevations mediated by influx from the extracellular space (Shigetomi et al., 2011; Malarkey et al., 2008) and/or release from the intracellular endoplasmic reticulum (ER) stores (Verkhratsky et al., 2012). IP₃-triggered Ca²⁺-induced Ca²⁺ release (CICR) from the ER is considered the primary mechanism responsible for

intracellular Ca^{2+} dynamics in astrocytes (Nimmerjahn, 2009; Volterra and Meldolesi, 2005). This mechanism, schematized in Figure 2A, is essentially controlled by the interplay of three fluxes: (1) a Ca^{2+} transfer from the cytosol to the ER (J_P) mediated by endoplasmic-reticulum Ca^{2+} -ATPase (SERCA) pumps which contributes to the maintenance of higher Ca^{2+} concentrations in the ER stores than in the cytosol; (2) a passive Ca^{2+} leak (J_L) from the ER to the cytosol that is driven by the Ca^{2+} gradient between the ER and the cytosol; and (3) an efflux (J_{NL}) from the ER to the cytosol through IP₃ receptor (IP₃R) channels, which depends both on IP₃ and Ca^{2+} concentrations in the cytosol in a nonlinear fashion (Shinohara et al., 2011; Bezprozvanny et al., 1991).

Cytosolic Ca²⁺ regulates IP₃Rs in a biphasic manner: Ca²⁺ release from the ER is potentiated at low cytosolic Ca²⁺ concentrations but is inhibited at higher Ca²⁺ concentrations (Bezprozvanny et al., 1991; Iino, 1990). On the other hand, IP₃ monotonically activates IP₃R channels at constant Ca²⁺ concentrations (Watras et al., 1991), but dynamically changes the Ca²⁺ sensitivity of the channel (Mak et al., 2003; Kaftan et al., 1997). At low, subsaturating IP₃ concentrations, the optimal Ca²⁺ concentration for IP₃R modulation becomes lower, whereas at very high IP₃ concentrations, channel activity persists at supramicromolar Ca²⁺ concentrations (Mak et al., 2003; Kaftan et al., 1997). Thus, the level of IP₃ determines the dynamics of intracellular Ca²⁺.

Both production and degradation of IP₃ depend on enzymes that are regulated by cytosolic Ca²⁺ (De Pittà et al., 2009; Berridge et al., 2003). These include Ca²⁺-dependent PLCδ-mediated IP₃ synthesis and Ca²⁺-dependent IP₃ degradation by IP₃ 3-kinase (IP₃-3K) and by inositol polyphosphate 5-phosphatase (IP-5P) (Figure 2A) (Rebecchi and Pentyala, 2000; Sims and Allbritton, 1998; Zhang et al., 1993). However, while the activity of IP₃-3K is stimulated by cytosolic Ca²⁺ (Communi et al., 1997), IP-5P is inhibited instead (Communi et al., 2001). This results in different mechanisms of IP₃ degradation depending on the Ca²⁺ concentration in the cytoplasm (Irvine et al., 2006; Sims and Allbritton, 1998). Thus, for example, for equally-expressed enzymes, at low Ca²⁺ concentrations, namely lower than 500 nM (De Pittà et al., 2009; Sims and Allbritton, 1998), IP₃ degradation is promoted by both IP-5P and IP₃-3K, whereas for

intermediate-to-high cytosolic Ca²⁺ concentrations, degradation by IP₃-3K becomes predominant (Sims and Allbritton, 1998). Theoretical investigation showed that the interplay of these two regimes is both necessary and sufficient to reproduce Ca²⁺ oscillations and pulsations observed experimentally (De Pittà et al., 2009).

Intracellular levels of IP₃ can also be controlled by gap junction mediated diffusion of IP₃ from other regions of the same astrocyte or from neighboring cells (Giaume et al., 2010) (i.e. the I/O pathway in Figure 1B). Moreover, synaptic glutamate (or other synaptic agents) can bind to astrocytic G protein-coupled receptors (GPCRs) like mGluRs that are directly linked to intracellular IP₃ production by PLCβ (Zur Nieden and Deitmer, 2006) (pathway **A** in Figure 1B). In this fashion, astrocytic Ca²⁺ dynamics triggered by synaptically-controlled IP₃ production can be regarded as a form of encoding information about activity in adjacent synapses.

Encoding of synaptic activity by astrocytic Ca²⁺ is likely multimodal, depending on many possible intracellular properties (Dupont et al., 2011; De Pittà et al., 2009; De Pittà et al., 2009; De Pittà et al., 2008). A widely adopted classification considers the amplitude and the frequency of Ca²⁺ increases from basal levels (De Pittà et al., 2009; De Pittà et al., 2008; Falcke, 2004; Berridge, 1997). In this view, as summarized in Figure 2B, synaptic activity reflected by different intracellular IP₃ concentrations (STIMULUS), is encoded by the modulation of Ca²⁺ oscillations and pulsations either in their amplitude (AM), their frequency (FM) or both (AFM). While available experimental data suggest a preferential FM mode of encoding (Pasti et al., 1997), AM and AFM encoding of synaptic activity are also plausible mechanisms given that the amplitude of Ca²⁺ response can strongly depend on the stimulation intensity (Torres et al., 2012; Di Castro et al., 2011; Panatier et al., 2011; Wang et al., 2006). This is the case for example, of synaptic inputs that occur rapidly one after the other whereby the ensuing intracellular Ca2+ concentration builds up as a cumulation of such inputs (Torres et al., 2012; Perea and Araque, 2005). In further support of the AM/AFM encoding is the experimental observation that glutamate exocytosis from the astrocyte occurs only when Ca²⁺ increases beyond a threshold concentration (Montana et al., 2006; Auld and Robitaille, 2003; Pasti et al., 2001; Parpura and Haydon, 2000; Newman and Zahs, 1997). Hence, astrocytic Ca²⁺ increases in response to synaptic activity would not systematically trigger the release of glutamate or other gliotransmitters from the astrocyte. Acting on the amplitude of astrocytic Ca²⁺ signals, AM/AFM encodings could constitute a way to regulate astrocytic gliotransmitter release by synaptic activity. Further experiments are needed to elucidate the nature of the Ca²⁺ threshold for astrocytic exocytosis since this latter might be gliotransmitter-specific (Montana et al., 2006). Accordingly, AM/AFM encoding of Ca²⁺ dynamics could vary from one gliotransmitter to another.

Experimental evidence suggests that Ca²⁺ dynamics does not simply mirror synaptic activity but is more complex, to a point that astrocytes have been proposed to perform genuine processing of synaptic information (Perea et al., 2009; Perea and Araque, 2005). This possibility follows from the complex network of IP₃ and Ca²⁺ signaling and subtends a scenario where Ca²⁺ could be only one of the players in the encoding and processing of synaptic activity by astrocytes (Mishra and Bhalla, 2002). Yet many, if not all, of the other signals underlying the complex cascade of biochemical reactions that link synaptically-released glutamate to CICR, could also carry out encoding and processing (Berridge et al., 2003; Barlow, 1996). Theoretical investigations suggested that IP₃ could also encode for the glutamate stimulation levels via a systematic AFM encoding (De Pittà et al., 2009) as shown in Figure 2C. When cytosolic Ca²⁺ levels are low, close to resting values, IP₃ generally increases with ongoing synaptic activity (Glu). With low Ca²⁺, the activity of IP₃-3K is reduced and the resulting IP₃ degradation slows down. The contribution to IP₃ production by Ca²⁺-dependent PLCδ is reduced as well, so that intracellular IP₃ mostly depends on the frequency of synaptic release. Rapid successions of synaptic release events produce crisp increases of IP₃ (essentially proportional to the number of successive synaptic release events) while, between two remote release events, IP₃ tends to relax to resting levels. As a result, IP₃ dynamics overall evolves as the integral of synaptic activity. If IP₃ reaches the CICR-triggering threshold, intracellular Ca2+ increases fast and so does IP3-3K activity. Then, IP3 is rapidly degraded and resting IP₃ levels are restored, thus resetting the integral of synaptic activity to initial values.

It is precisely the alternation between these two different phases of IP₃ degradation (a high Ca²⁺-high IP₃-3K-activity phase and a low Ca²⁺-low IP₃-3K-activity phase), that endows IP₃ signal with high amplitude variability. On the other hand, such AM features still allow fast variations, thus rich spectral content (i.e. FM features), in response to changes in frequency of synaptic release. This enticing possibility could endow the IP₃ signal with the necessary properties to function as optimal interface between synaptic stimuli and intracellular Ca²⁺ signals. Since neural information is carried by the timing of spikes rather than by their amplitude (Sejnowski and Paulsen, 2006), the capability of fast highly-variable amplitude changes corresponding to rich spectral content of IP₃ signals, would fulfill this requirement, embedding the essential spectral features of the synaptic signal into the spectrum of the IP₃ transduction. On the other hand, because Ca²⁺ signals are triggered primarily by suprathreshold IP₃ elevations (Keizer et al., 1995; Li et al., 1994), the coexistence of AM features within the AFM IP₃ signal seems to be a necessary prerequisite in order to trigger CICR.

This could also help elucidate the origin of the integrative properties of Ca²⁺ signaling in astrocytes (Perea et al., 2009). These properties could result from at least two steps of integration: one step is the transduction of the agonist signal into the IP₃ signal; the other step is the cross-talk between IP₃ and Ca²⁺ signals. Hence, AFM-encoding IP₃ dynamics could operate a first preliminary integration by smoothing the highly indented synaptic stimulus. The inherent features of CICR would then bring forth a further integration step, yielding Ca²⁺ patterns that are even smoother than IP₃ signals (De Pittà et al., 2009).

The tight dynamical coupling between IP₃ and Ca²⁺ signals also suggests that the way astrocytes process synaptic signals, i.e. their frequency response to synaptic stimuli, is not fixed but rather dynamical and dependent on the history of activation of the astrocyte. This is because different IP₃ signaling mechanisms that are dynamically regulated by Ca²⁺ likely correspond to different frequency responses of the astrocyte with respect to synaptic signals. Figure 2D shows the time course of IP₃ production (IP₃ prod.) and degradation (IP₃ degr.) (dashed black lines) underlying simulated IP₃ and Ca²⁺ signals (top panel, green and black traces respectively) in response to two events of synaptic glutamate release (bottom panel). While Ca²⁺-dependent IP₃ production brought forth

by PLCβ (*cyan trace*) and PLCδ (*pink trace*) enzymes could modulate the threshold frequency of synaptic stimuli that triggers Ca²⁺ signaling in the astrocyte, the existence of different regimes of IP₃ degradation within a single Ca²⁺ oscillation cycle could be responsible for different cutoff frequencies of synaptic release beyond which Ca²⁺ mediated astrocyte processing of synaptic stimuli ceases. In particular the cutoff frequency during low IP₃-3K activity could be mainly set by the rate of IP₃ degradation by IP-5P (*orange trace*). When Ca²⁺ is high instead, IP₃ degradation by IP₃-3K (*purple trace*) could also become very strong, thus sensibly reducing the cutoff frequency. That is, the cutoff frequency is dependent on the context of underlying Ca²⁺ signaling which in turn depends on the history of activation of the astrocyte by synaptic stimuli.

The subcellular arrangement of the enzymes underlying IP₃ signaling could also be responsible for spatial heterogeneity of the frequency response of the astrocyte. Although the subcellular localization of IP₃ production and degradation enzymes in astrocytes remains to be elucidated, studies in brain tissue suggest that PLCβ and IP-5P could localize mainly in proximity to the plasma membrane, whereas PLCδ and IP₃-3K are preferentially in the cytoplasm (Irvine et al., 2006; Rebecchi and Pentyala, 2000). Given that the ER distribution changes from astrocytic processes to soma (Pivneva et al., 2008), different subcellular regions of the astrocyte could correspond to different cytoplasmic volumes and thus to distinctly different expressions of enzymes mediating IP₃ signaling. The ensuing different subcellular arrangement of these enzymes could ultimately provide anatomical specificity to the astrocytic phosphoinositide signaling which underlies CICR-based astrocyte processing of synaptic activity (Fukaya et al., 2008). In this fashion, processing of synaptic stimuli by Ca²⁺ signaling at astrocytic processes could differ from that carried out in the soma by means of differently expressed IP₃ signaling-related enzymes.

Computational aspects of propagating Ca²⁺ signals

Intracellular and intercellular propagation of Ca²⁺ could contribute new encoding and processing modes, in addition to those depicted in Figure 2B. However, despite the numerous modeling studies developed to account for the rich dynamics of astrocyte Ca²⁺

signaling (Dupont et al., 2011; Goldberg et al., 2010; Bennett et al., 2008); for a recent review on calcium modeling see (Falcke, 2004), we still lack a comprehensive theoretical framework to link the local Ca²⁺ signals that are restricted to small regions of the astrocytic processes, to their spatial dynamics and their possible propagation at larger spatial scales: intracellular propagation, global whole-cell signals or cell-to-cell Ca²⁺ waves.

Propagations at these various scales probably differ by their underlying mechanisms (Scemes and Giaume, 2006; Falcke, 2004). Fast-rising and short-lived local Ca²⁺ events, observed in response to even a single quantal release from synaptic terminals (Di Castro et al., 2011; Panatier et al., 2011) closely resemble spatially confined Ca²⁺ puffs or blips in other cell types (Bootman et al., 2001; Thomas et al., 2000) and could depend on spatial clustering of IP₃Rs along the ER structures or of mGluRs along the plasma membrane, or on both (Arizono et al., 2012; Panatier et al., 2011; Marchaland et al., 2008). The cumulative recruitment of these Ca²⁺ puffs could lead to spatially more extended Ca²⁺ events which could either be still confined within astrocytic processes (Di Castro et al., 2011) or propagate to other cellular regions or to other cells as regenerative Ca²⁺ waves (Kuga et al., 2011; Pasti et al., 1997).

Calcium could propagate by at least two routes (for a recent review see (Scemes and Giaume, 2006). One is intracellular, through gap junction channels, involving diffusion of IP₃ directly from cytoplasm to cytoplasm. The other route is extracellular, involving release of ATP from the astrocyte which binds to GPCRs of the same cell or neighboring astrocytes, increasing their IP₃ levels (Guthrie et al., 1999). The relative contribution of each of these pathways likely depends on developmental, regional and physiological states and could subtend different ranges of propagations as well as different temporal features (Giaume et al., 2010; Haas et al., 2006; Scemes and Giaume, 2006).

The restriction and clustering of mGluRs expression along astrocytic processes to subregions that colocalize with synaptic terminals (Arizono et al., 2012; van den Pol et al., 1995) hints the possibility of a subcellular compartmentalization of Ca²⁺ signals (Di Castro et al., 2011; Panatier et al., 2011; Marchaland et al., 2008). Local Ca²⁺ events would be spatially restricted to narrow regions around each mGluRs cluster thus defining independent signals within the same process. In this fashion, astrocytes could carry out

parallel integration and processing of synaptic information on different temporal and spatial scales at different processes (Bernardinelli et al., 2011; Goldberg et al., 2010) or even in different subregions of the same process which could constitute separate functional microdomains (Panatier et al., 2011). Furthermore, the resulting neuromodulatory action exerted by astrocytic gliotransmitters on synaptic terminals and their impact on neuronal network activity could vary from one process or microdomain to the other (Navarrete and Araque, 2011).

The spatial scale and the time window of Ca²⁺ events likely discriminate between different mechanisms of IP₃ and Ca²⁺ signaling. At the level of astrocytic processes and subcellular compartments, Ca²⁺ propagation could be mediated by fast intracellular IP₃ linear (i.e. Fickian) diffusion (Falcke, 2004; Sneyd et al., 1994). On the other hand, when considering intercellular propagation mediated by gap junctions, IP₃ transport from one cell to the other could be essentially nonlinear. This scenario was shown to be consistent with the observed variability of Ca²⁺ wave propagation distance (Goldberg et al., 2010) and could explain the long-range regenerative propagation of Ca²⁺ waves observed in cortical astrocytes (Scemes and Giaume, 2006; Tian et al., 2006).

Cell heterogeneity likely constitutes an additional critical aspect that substantially affects the propagation patterns and the extent of propagation of Ca²⁺ signals (Iacobas et al., 2006; Goldberg et al., 2010; De Pittà et al., 2008). This possibility is illustrated in Figure 2E by a toy example consisting of a heterogeneous linear chain of FM-encoding (*red traces*) and AFM-encoding (*green traces*) astrocytes. The synaptic stimulus is restricted to the first cell of the chain (i.e. cell number 1). Only FM-encoding cells guarantee regenerative propagation of Ca²⁺ signals, whereas AFM cells do not, acting like propagation barriers along the chain. Unlike in AFM cells, Ca²⁺-dependent IP₃ production in FM cells guarantees IP₃ diffusion to the next cell in the chain to levels that are beyond the threshold of CICR thus promoting regenerative propagation (Goldberg et al., 2010). Moreover, the shape of the local Ca²⁺ events in each cell changes along the propagation path: after each AFM cell, the frequency of FM-encoding Ca²⁺ pulses is reduced, suggesting that different propagation patterns could carry out different processing of synaptic information (Goldberg et al., 2010).

The above scenario hints that the spatial distribution of astrocytes in different brain areas could be made to fulfill specific processing tasks. Indeed neighboring astrocytes in the brain are believed to be distributed in space in a nonrandom orderly fashion called "contact spacing" (Volterra and Meldolesi, 2005; Chan-Ling and Stone, 1991) or "tiling", where each astrocyte creates its micro-anatomical domain with its processes overlapping with adjacent astrocytes only at their periphery (Bushong et al., 2002). Such spatial arrangement, combined with the heterogeneity of astrocytic responses could be important in intercellular Ca²⁺ wave propagations and the related computational tasks carried out by astrocyte networks. The latter could be relevant in particular, for the emergence of astrocytic functional maps observed in several brain areas (Giaume et al., 2010).

Increasing evidence argues in fact for a functional organization of astrocytes, reminiscent of that of cortical neurons (Bernardinelli et al., 2011). In the ferret visual cortex astrocytes, like neurons, respond to visual stimuli, with distinct spatial receptive fields and sharp tuning to visual stimulus features, including orientation and spatial frequency (Schummers et al., 2008). The stimulus-feature preferences of astrocytes there can be mapped across the cortical surface, in close register with neuronal maps (Schummers et al., 2008). Similar observations were also reported for astrocytes in the motor cortex (Haas et al., 2006) and in the somatosensory cortex (Schipke et al., 2008) as well as in the olfactory bulb (De Saint Jan and Westbrook, 2005).

Anatomical compartmentalization of astrocyte networks could underlie such functional organization. Both in the somatosensory barrel cortex and in the olfactory bulb, astrocytes are preferentially connected by gap junctions within the same barrel or olfactory glumerulus rather than between adjacent barrels or glomeruli (Roux et al., 2011; Houades et al., 2008). However spatial confinement of gap junctions within single barrels/glumeruli might not fully account for the selective activation of astrocyte by electrical stimulation. Indeed, similar Ca²⁺ signals in response to the same stimulus could be observed in the same barrel yet with pharmacological block of astrocyte gap junctions (Schipke et al., 2008). Thus, additional factors must contribute to the astrocyte tuned response, which likely emerges as a result of the dynamical interactions with surrounding neurons (Rouach et al., 2004) and could ultimately depend on location and nature of activated cells among the other astrocytes in the network (García-Marqués and Lópes-

Mascaraque, 2012; Matyash and Kettenmann, 2010). In the case of Figure 2E, for example, stimulated FM-encoding cells could trigger Ca²⁺ signaling in neighboring cells in a regenerative fashion thus extending their tuned response in space. On the other hand, AFM cells, acting as propagation barriers, could shape the borders of this tuned response, eventually drawing the topographical features of the ensuing functional map (Lallouette and Berry, 2012).

Relating Ca²⁺ signals to gliotransmitter exocytosis from the astrocyte

There is a number of possible routes by which astrocytes could release gliotransmitters (Zorec et al., 2012; Parpura and Zorec, 2010; Ni et al., 2007), but Ca2+-dependent exocytosis is likely the major one on a physiological basis (Parpura et al., 2011; Barres, 2008). However, the identity of the incoming inputs, the underlying molecular mechanism and the physiological conditions that govern gliotransmitter exocytosis largely remain to be elucidated (Parpura and Zorec, 2010; Santello and Volterra, 2009; Ni et al., 2007; Montana et al., 2006). Calcium-dependent exocytosis of glutamate or ATP from astrocytes, for example, may strictly depend on the nature of the upstream Ca²⁺ signal (Malarkey and Parpura, 2011; Li et al., 2008; Marchaland et al., 2008; Pryazhnikov and Khiroug, 2008; Perea and Araque, 2005); including the type of neurotransmitter involved and the type of receptor engaged (Blomstrand and Giaume, 2006; Bezzi et al., 2004; Coco et al., 2003; Muyderman et al., 2001; Enkvist and McCarthy, 1992). The influence of astrocytic glutamate or ATP on synaptic activity also likely depends both on the type of incoming stimulus and on the specific localization of the engaged receptor in the astrocyte (Santello and Volterra, 2009; Perea and Araque, 2005).

A large amount of evidence suggests that gliotransmitter exocytosis from astrocytes bears several similarities with its synaptic homologous (Bergersen et al., 2011; Bergersen and Gundersen, 2009; Santello and Volterra, 2009) (Figure 3A). Astrocytes possess vesicular compartments that are competent for the regulated exocytosis of glutamate (Bergersen and Gundersen, 2009; Bezzi et al., 2004) and ATP (Jaiswal et al., 2007; Zhang et al., 2007; Coco et al., 2003). Similarly to synapses, astrocytes express SNARE proteins necessary for exocytosis (Schubert et al., 2011; Parpura et al., 1995) as well as proteins

responsible for concentrating glutamate or ATP into vesicles (Sawada et al., 2008; Bezzi et al., 2004; Montana et al., 2004; Zhang et al., 2004). Fusion with the plasma membrane, trafficking and recycling of astrocytic glutamate and ATP secretory vesicles have been observed (Jaiswal et al., 2007; Pangršic et al., 2007; Stenovec et al., 2007; Chen et al., 2005; Crippa et al., 2006; Bezzi et al., 2004), which are indicative of quantal glutamate and ATP release (Del Castillo and Katz, 1954; Santello et al., 2011; Marchaland et al., 2008; Jaiswal et al., 2007; Pangršic et al., 2007; Domercq et al., 2006; Pasti et al., 2001). Glutamate exocytosis from cultured astrocytes evoked by GPCRs is observed with short delay, i.e. 50 - 100 ms, after the rise in submembrane Ca^{2+} , and is mediated by a rapid succession of fusion events which peaks within ~500 ms from the onset and decays to baseline much more slowly (>1 s), though generally before the recovery of basal Ca²⁺ levels (Santello et al., 2011; Marchaland et al., 2008; Domercq et al., 2006) (refer also to Table 2). In addition to this "exocytotic burst", larger delays with slower rate of sustained vesicular fusion events have also been reported (Malarkey and Parpura, 2011; Kreft et al., 2004). The delayed onset with respect to the Ca²⁺ rise is consistent with a threshold Ca²⁺ concentration for release (Pasti et al., 1997; Parpura and Haydon, 2000). On the other hand the overall release of glutamate is characterized by a rising phase much faster than its decay and can be approximated by an exponential function like synaptic exocytosis vet with a decay time much slower than the latter (De Pittà et al., 2011; Santello et al., 2011; Marchaland et al., 2008) (Figure 3B). Although much less characterized than its glutamate counterpart, astrocytic ATP exocytosis could occur in a qualitatively similar fashion in spite of different underlying kinetics (Li et al., 2008; Pryazhnikov and Khiroug, 2008; Pangršic et al., 2007). Based on these arguments, it was proposed that astrocytic gliotransmitter release could be modeled using the same mathematical description of synaptic release, although the two mechanisms are likely different in their molecular machinery, with the kinetics of astrocyte release much slower than synaptic release (De Pittà et al., 2011; Schubert et al., 2011).

How are different modes of Ca²⁺ encoding translated into glutamate or ATP release? Assuming proper conditions about the rate of clearance of these gliotransmitters with respect to the underlying intracellular Ca²⁺ dynamics that mediate their exocytosis (Abbracchio et al., 2009), an intriguing theoretical prediction is that various patterns

of Ca²⁺ oscillations could mostly correspond to different rates of gliotransmitter release (De Pittà et al., 2011). This is presented in Figure 3C where, for three stereotypical patterns of Ca²⁺ oscillations, that is AM, FM and AFM, the corresponding timing of gliotransmitter release from the astrocyte is shown. In this example, FM-encoding Ca²⁺ oscillations always cross the threshold for exocytosis (*dashed red line*), triggering gliotransmitter release every time. Conversely, AM or AFM oscillations may not be large enough to reach such a threshold, resulting in some oscillations that fail to trigger gliotransmitter release. In this fashion, while the FM Ca²⁺ oscillations trigger gliotransmitter exocytosis at their own frequency, the amplitude of AM and AFM oscillations could selectively discriminate which Ca²⁺ pulse triggers exocytosis, eventually dictating the frequency of "measured" glutamate or ATP release events (De Pittà et al., 2011). Further experimental investigations are required to elucidate whether such prediction could effectively mimic reality.

While astrocytic Ca²⁺ signals could be triggered both by spontaneous and evoked synaptic release, gliotransmitter release might be not (Di Castro et al., 2011; Panatier et al., 2011). Blockade of Ca²⁺-dependent glutamate release in astrocytes in the dentate gyrus was indeed observed to be effective in reducing the frequency of synaptic release events only when these were evoked by action potentials, but not when they happened spontaneously. This suggests that release of glutamate from astrocytes in this region could effectively occur only in presence of evoked synaptic activity (Di Castro et al., 2011). Interestingly, the Ca²⁺ elevations in astrocyte processes triggered by action potentials were reported to be more complex, larger in amplitude and more extended in space, than those generated by spontaneous synaptic release events. Since glutamate could be released from several sites along the same astrocyte process and this latter could contact several synapses (Panatier et al., 2011), one of such Ca²⁺ elevations could then generate multiple spatially-distinct glutamate release events modulating synaptic release at several other synapses. The same Ca²⁺ elevation however, could bring forth at subcellular regions of the process, different local Ca²⁺ dynamics, in close analogy to the behavior of the heterogeneous AM/AFM oscillations in the astrocyte chain in Figure 2E. Such different local Ca²⁺ dynamics could in turn result in different rates of glutamate release and thus in different modulations of synaptic release in a nonrandom fashion. In

this way, the same astrocytic process or a segment of it, could carry out multiple regional modulations of synaptic release, depending both on the temporal and spatial dynamics of synaptic release. It is however possible that the mechanisms underlying Ca²⁺-dependent gliotransmission differ in different brain areas (Matyash and Kettenmann, 2010; Zhang and Barres, 2010). Indeed, in contrast with the above observations in the dentate gyrus, astrocytes in the stratum radiatum of the hippocampus were reported to release glutamate even in the absence of synaptic activity evoked by action potentials (Bonansco et al., 2011).

Another issue is what makes a single astrocyte release one gliotransmitter rather than another. A possibility is that different gliotransmitters are released in response to different stimuli. In situ studies indeed suggest that purinergic GPCR-mediated astrocytic Ca²⁺ signals could preferentially trigger glutamate release (Di Castro et al., 2011; Jourdain et al., 2007; Perea and Arague, 2007) (see also Table 1). In contrast, Ca²⁺ elevations triggered by glutamate could bring forth ATP release (Panatier et al., 2011; Gordon et al., 2009; Pascual et al., 2005). Overall these observations hint that a tight association likely exists between the type of targeted astrocytic receptor and the secretory machinery of gliotransmitters (Zorec et al., 2012). Moreover, in the same astrocyte, different gliotransmitters could be contained in different organelles with different secretory properties in response to Ca²⁺ signals (Coco et al., 2003). Indeed while glutamate seems to be preferentially released by synaptic-like microvesicles (Bergersen et al., 2011; Jourdain et al., 2007; Bezzi et al., 2004), ATP is likely released by densecore granules (Coco et al., 2003) and/or lysosomes (Li et al., 2008; Jaiswal et al., 2007; Zhang et al., 2007). Although the underlying molecular machinery of exocytosis remains to be elucidated, each organelle population is likely secreted in a different fashion (Pryazhnikov and Khiroug, 2008). In vitro evidence showed in fact that Ca2+ signals that triggered release of glutamate-containing vesicles (Marchaland et al., 2008) did not release ATP-filled organelles and viceversa (Li et al., 2008; Coco et al., 2003), ultimately suggesting that glutamate and ATP could be released in response to different Ca²⁺ signals (Parpura and Zorec, 2010).

Intriguingly, stimulation of astrocyte GPCRs can evoke fast gliotransmitter exocytosis within few hundreds of milliseconds (Santello et al., 2011; Marchaland et al., 2008;

Domercq et al., 2006; Bezzi et al., 2004), indicating that the Ca²⁺-dependent process that couples stimulus with secretion must be fast. Indeed, the peak of GPCRmediated Ca²⁺ release from the ER can be as fast as 50-250 ms ((Di Castro et al., 2011; Panatier et al., 2011; Marchaland et al., 2008) and Ca²⁺-dependent exocytosis of single glutamate vesicles can occur within less than 5 – 20 ms from Ca²⁺ elevation (Santello et al., 2011; Marchaland et al., 2008; Bowser and Khakh, 2007; Chen et al., 2005). Therefore, to assure fast stimulus-secretion coupling, IP₃ diffusion from the site of production by GPCRs at the plasma membrane to IP₃ receptors on the ER membrane must also be of the order of tens of milliseconds and so must Ca²⁺ diffusion from the mouth of IP₃Rs to the Ca²⁺ sensor of exocytosis (Ni et al., 2007; Zhang et al., 2003). Given that the diffusion times of IP₃ or Ca²⁺ can be estimated as the half of the square of the diffusion distance from the site of their production in the cytoplasm divided by the respective diffusion constants (Syková and Nicholson, 2008), which can be as high as $\sim 200 - 300 \text{ um}^2/\text{s}$ for IP₃ (Snevd et al., 1994; Allbritton et al., 1992) and 30 um²/s for Ca²⁺ (Kang and Othmer, 2009), then diffusion times of the order of milliseconds could be obtained only for diffusion lengths at most in the micron range. This prediction is fully supported by the functional evidence of local GPCR-evoked, ER-dependent Ca²⁺ microdomains in astrocytic processes (Di Castro et al., 2011; Panatier et al., 2011) and by the morphological evidence that at astrocytic processes the ER stores are found at ~200 – 600 nm distance both from the plasma membrane and gliotransmitter-containing vesicles (Bergersen et al., 2011; Marchaland et al., 2008; Bezzi et al., 2004). Moreover, GPCR agonist-mediated Ca2+ transients were observed in restricted subplasma areas in close proximity to the sites of exocytosis (Marchaland et al., 2008), suggesting that both GPCRs and secretory vesicles must be spatially close to the IP₃Rs responsible for Ca²⁺ release from the ER. This indicates that the location of IP₃Rs along the ER membrane in astrocyte processes might be nonrandom (Blaustein and Golovina, 2001), in tight spatial association with astrocytic GPCRs on the plasma membrane and releasable gliotransmitter organelles (Panatier et al., 2011; Marchaland et al., 2008). Such spatial coupling could ultimately underlie the preferential occurrence of functional gliotransmission from astrocytic processes rather than from the soma (Gordon et al.,

2009), entailing strict spatiotemporal requirements for Ca²⁺ signals to trigger release of gliotransmitters from the astrocyte and modulate synaptic transmission.

Modulation of synaptic release by astrocytic glutamate and ATP

Astrocyte-derived glutamate and ATP or adenosine can modulate synaptic transmission, either increasing neurotransmitter release (Bonansco et al., 2011; Di Castro et al., 2011; Panatier et al., 2011; Jourdain et al., 2007; Perea and Araque, 2007; Fiacco and McCarthy, 2004; Araque et al., 1998) or decreasing it (Andersson and Hanse, 2011; Andersson and Hanse, 2010; Pascual et al., 2005; Zhang et al., 2003) depending on the type of presynaptic receptor involved and the brain area (pathway **B** in Figure 1B; see also Table 1). At excitatory synapses in the hippocampal dentate gyrus, glutamate is released from surrounding astrocytic processes in close proximity to presynaptic NR₂Bcontaining NMDA receptors (Figure 4A). Activation of these receptors results in increased synaptic release and strengthening of synaptic transmission (Jourdain et al., 2007). At Schaffer collateral synapses in the CA1 hippocampal area a similar effect is mediated by presynaptic mGluRs (Perea and Araque, 2007; Fiacco and McCarthy, 2004). Besides directly targeting presynaptic receptors, astrocyte-released glutamate could also bind ionotropic receptors found along the axons of hippocampal CA3 pyramidal cells, broadening the profile of propagating action potentials (APs) (Sasaki et al., 2011). The broadened APs in turn, trigger larger Ca²⁺ elevations in presynaptic boutons, resulting in larger synaptic release probability.

Conversely, astrocyte-released ATP and its derivative adenosine, bind to presynaptic purinergic receptors, i.e. P_2Y_1Rs or A_1Rs respectively, decreasing synaptic release (Pascual et al., 2005; Zhang et al., 2003). However, astrocyte-derived adenosine, could also target A_{2A} receptors which can increase synaptic release (Panatier et al., 2011) (omitted from Figures 1A and 4A for simplicity). Both effects of adenosine – inhibitory via A_1Rs and stimulatory via A_2Rs – have been described at hippocampal CA3-CA1 synapses (Panatier et al., 2011; Serrano et al., 2006; Pascual et al., 2005; Zhang et al., 2003), and the prevalence of one on the other likely depends on the level of synaptic activity (Panatier et al., 2011). This would be in line with observations at the frog's neuromuscular junction, where different stimulations of the tibial nerve differentially activated A_1Rs or A_2Rs in association with different Ca^{2+} dynamics in the peri-

junctional glial cell (Todd et al., 2010). Intriguingly, at hippocampal synapses different synaptic stimuli could differentially change the morphology of astrocyte perisynaptic processes (Lavialle et al., 2011; Haber et al., 2006) thus reshaping, in an activity-dependent fashion, the extracellular space of interaction between astrocyte-derived adenosine and presynaptic receptors. This could dynamically regulate access of adenosine to one receptor with respect to the other (Syková and Nicholson, 2008; Haber et al., 2006) ultimately modulating synaptic release in a complex fashion. The functional consequences of astrocytic remodeling was indeed demonstrated in the supraoptic nucleus, where dynamic changes in the astrocytic wrapping of synapses during lactation could regulate the extent of synaptic glutamate spillover and thereby control heterosynaptic depression of GABAergic transmission by presynaptic mGluRs (Piet et al., 2004; Oliet et al., 2001).

The opposite effects due to astrocytic glutamate or ATP/adenosine could endow astrocytes with the capacity to exert non-stereotyped bimodal control of synaptic transmission (Volterra and Meldolesi, 2005). On the other hand, the temporal concurrence of both these effects due to co-expression of inhibitory and stimulatory receptors at the same synaptic terminals (Rebola et al., 2005; Shigemoto et al., 1997), could result in occlusion, i.e. no net effect on synaptic release by the astrocyte (De Pittà et al., 2011). Alternatively, balanced activation (and possibly occlusion) of A_1 and A_{2A} receptors by astrocyte-derived adenosine could set synaptic release in basal conditions (Panatier et al., 2011). Hence, the ensuing regulation of synaptic transmission triggered by gliotransmitters in response to stimuli, could result instead from an unbalance of activation of these receptors rather than by the distinct activation of one receptor type with respect to the other, ultimately providing a high degree of complexity in the control of synaptic transmission by astrocytes. For the sake of clarity, in the following we will consider only release-decreasing effects of astrocyte ATP or its derivative, adenosine.

The details of the biochemical mechanism underlying modulation of synaptic release by astrocytic glutamate or ATP (or adenosine) likely depend on the type of targeted presynaptic receptors and are not fully understood (Pinheiro and Mulle, 2008). The simplest explanation would be that astrocytic glutamate and ATP lead to a modulation of presynaptic intracellular Ca²⁺ levels which eventually results in a modulation of synaptic

release probability (Pinheiro and Mulle, 2008; Zucker and Regehr, 2002) with significant repercussions on synaptic plasticity, including short-term depression and facilitation.

Short-term facilitation and depression can be assessed by measuring the paired-pulse ratio (PPR), i.e. the ratio between the amplitudes of successive postsynaptic currents (PSCs) recorded in response to a pair of action potentials in rapid succession as illustrated in Figure 4B (Zucker and Regehr, 2002). When the value of the peak postsynaptic current associated to the second incoming spike is larger than the peak current recorded in coincidence with the first spike (*green traces*), then synaptic release is increasing for incoming spikes, i.e. facilitation occurs, and the corresponding PPR is larger than unity. Conversely, when the second peak is less than the first peak (*magenta traces*), this marks a decrease of neurotransmitter release from the presynaptic terminal which reflects depression, and the corresponding value of PPR is less than one. It should be noted that by varying the interval between two pulses the same synapse can be either depressed or facilitated. For simplicity we omit the interpulse interval as a variable in this description.

In general, in basal conditions, i.e. in response to an individual action potential, the value of synaptic release probability of an individual synapse or of an ensemble of synapses defines the nature of synaptic transmission at that synapse/ensemble, namely whether it is facilitating or depressing, with low values of probability favoring facilitation and high values favoring depression (Abbott and Regehr, 2004) (Figure 4B, right). Thus, any modulation of synaptic release probability by gliotransmitters that changes the PPR from below unity to values above it or vice versa, could switch the mode of synaptic transmission from depressing to facilitating or vice versa. This scenario was theoretically addressed in (De Pittà et al., 2011) and it was shown to substantially agree with experiments. Indeed, at hippocampal synapses, the increase of synaptic release probability due to astrocytic glutamate correlates with a decrease of the PPR (Bonansco et al., 2011; Jourdain et al., 2007; Perea and Araque, 2007). Conversely, a decrease of synaptic release due to the action of astrocyte-derived ATP (or adenosine) is accompanied by an increase of the PPR (Zhang et al., 2003). The frequency of astrocytic glutamate (Glu) and/or ATP exocytosis are likely crucial in the regulation of the extent of the modulation of synaptic release by astrocytes (De Pittà et al., 2011), a principle

illustrated in Figure 4C. This figure shows the simulated peak postsynaptic currents for the same synapse in response to 100 trials of presynaptic spike trains with identical statistics (*raster plots*). Each column in Figure 4C corresponds to a different frequency of astrocytic Ca²⁺ pulses (*top row*), yielding to different frequencies of gliotransmitter release when Ca²⁺ crosses the threshold for exocytosis (*dashed red line*) (see also Figure 3B). Colors in the raster plots refer to paired-pulse plasticity quantified by PPR. For two consecutive presynaptic spikes, if the second spike releases synaptic neurotransmitter more than the first spike, then it is PPR > 1, paired-pulse facilitation is observed, and the peak postsynaptic current associated to the second spike is colored in *green*. Vice versa, if the amount of neurotransmitter released by the second spike is less than that released by the first one, then PPR < 1, that is paired-pulse depression occurs, and the second peak postsynaptic current is colored in *magenta*.

In absence of astrocytic gliotransmitter (left column), the raster plot of a facilitating synapse (*middle row*) shows predominant paired-pulse facilitation, i.e. mostly green dots. However, in presence of release of glutamate from the astrocyte (+Glu), as explained above, the stimulatory effect of this gliotransmitter on synaptic release changes pairedpulse plasticity which is marked by the appearance of *magenta* bands in the raster plots (middle and right columns). These bands locate time intervals where paired-pulse depression becomes prominent (i.e. predominance of magenta dots) on the overall pairedpulse facilitation background (green dots). Notably these bands are almost in coincidence with glutamate release from the astrocyte (top row) and their number increases with the glutamate release frequency. Therefore, for the same time window, the same originallyfacilitating synapse gets increasingly depressing as the rate of glutamate release from the astrocyte increases. The opposite is observed for an otherwise depressing synapse (i.e. predominance of paired-pulse depression, thus mostly magenta dots in the bottom left raster plot). In this case, in presence of release of ATP and its derivative adenosine (+ATP/Adn) from the astrocyte, due to the inhibitory effect of astrocytederived purines on synaptic release considered in this example, green bands appear in the raster plots which mark the onset of periods of predominant paired-pulse facilitation. The number of these bands grows for higher rates of ATP release from the astrocyte so that the same originally-depressing synapse behaves more akin of a facilitating one as the rate of ATP release from the astrocyte increases.

An intriguing prediction that follows from the above arguments is that the frequency of gliotransmitter release, by modulating synaptic release probability at basal conditions, could dynamically control the nature of synaptic transmission as elucidated in Figure 5A. In particular, under certain conditions, a threshold frequency for gliotransmitter release (*blue line*) could exist above which the astrocyte can switch the nature of synaptic transmission, turning depressing synapses into facilitating or vice versa, facilitating synapses into depressing (De Pittà et al., 2011). Hence, the plasticity mode at such synapses is not fixed but rather it is set by the release rate of gliotransmitters from neighboring astrocytic processes.

Remarkably, the threshold frequency of gliotransmitter release that discriminates between facilitation and depression at one synapse can be as low as 0.05 Hz or less (as in the case of Figure 5A) thus falling within the range of Ca²⁺ oscillations observed in astrocytes in basal conditions (Bonansco et al., 2011; Di Castro et al., 2011; Parri et al., 2001; Aguado et al., 2002). In such conditions as shown in Figure 5B (top), intracellular Ca²⁺ levels in astrocytes spontaneously fluctuate in a highly stochastic fashion (Di Castro et al., 2011; Hirase et al., 2004) and can similarly cross the threshold for gliotransmitter release. The ensuing release of gliotransmitter, however, could be sufficient to tonically set the basal tone of synaptic transmission (Figure 5B). Inasmuch as the rate of gliotransmitter release could also correlate with the incoming synaptic stimulus through Ca²⁺ dynamics in the astrocytes (Di Castro et al., 2011; Aguado et al., 2002), this scenario discloses the possibility that astrocytes act as endogenous regulators of the efficacy of synaptic transmission (Di Castro et al., 2011; Panatier et al., 2011; Giaume et al., 2010; Halassa and Haydon, 2010; Haydon, 2001). That is, through integration of synaptic activity by means of their Ca²⁺ signals, astrocytes could adapt synaptic strength according to the history of the synapse.

Implications of astrocyte modulation of synaptic transmission and plasticity

The effect of modulation of synaptic release probability by astrocytic gliotransmitters may decay more slowly than the Ca²⁺ elevation triggering astrocyte exocytosis (Serrano et al., 2006; Fiacco and McCarthy, 2004), and still be present upon gliotransmitter release by following Ca²⁺ increases (Volman et al., 2007). Therefore astrocytic Ca²⁺ activity resulting in high rates of gliotransmitter release, could bring forth long-lasting modulations of synaptic release. Insofar as synaptically-released neurotransmitter could shape postsynaptic signaling at the basis of long-term synaptic plasticity (Bliss and Collingridge, 1993), persistent modulations of synaptic release probability by astrocyte could ultimately contribute to long-term changes of synaptic strength underlying neural processing, memory formation and storage of information. Support to this scenario comes from studies on hippocampal synapses for which the temporal coincidence of postsynaptic depolarization with the increase of Ca²⁺ elevations in neighboring astrocytes was shown to induce long-term potentiation (LTP) of synaptic transmission (Navarrete et al., 2012; Navarrete and Araque, 2010; Perea and Araque, 2007). Notably, this form of LTP is independent of the activation of postsynaptic NMDARs but rather, it depends on glutamate released from astrocytes, which persistently potentiates synaptic transmitter release through activation of presynaptic mGluRs (Perea and Araque, 2007). On the other hand, at synapses between excitatory neurons in layers 4 and 2/3 in the rat barrel cortex, activity-dependent induction of long-term depression (LTD) also requires astrocyte Ca2+ signaling (Min and Nevian, 2012). At these synapses, postsynaptically-released endocannabinoids mediate Ca²⁺-dependent release of glutamate from astrocytes which targets presynaptic NMDARs bringing forth LTD (Rodríguez-Moreno and Paulsen, 2008; Sjöström et al., 2003).

The differential induction of LTP and LTD in neighboring synapses has been suggested to determine the size and shape of cortical functional topographic units such as ocular dominance columns in the primary visual cortex and whisker barrels in the primary somatosensory cortex (Li et al., 2009; Feldman and Brecht, 2005; Hensch, 2005). Thus, the possible involvement of astrocytes in LTP and LTD suggests that these cells could

contribute to the plasticity of cortical maps and the development of corresponding sensory representations (Rossi, 2012).

Modulation of synaptic release probability by astrocytic gliotransmitters could also alter the temporal order of correlated pre- and postsynaptic spiking that critically dictates spike-timing-dependent plasticity (STDP) (Pascual et al., 2005). Inhibition of spontaneous glutamate release from astrocytes in hippocampal CA1 synapses, consistent with a decrease of synaptic release probability, was indeed reported to modify the threshold for induction of spike-timing-dependent LTP (Bonansco et al., 2011). In this fashion, astrocytes by gliotransmission-mediated regulations of synaptic release probability could control not only different mechanisms of synaptic plasticity but also the threshold of synaptic activity required for their onset, thus playing a role in metaplasticity too, that is the plasticity of synaptic plasticity (Abraham, 2008).

Gliotransmitters do not control synaptic plasticity only via presynaptic actions, but also by actions on postsynaptic receptors. Indeed, the induction of LTP itself appears to be uniquely controlled by astrocytes through the release of D-serine (Santello and Volterra, 2010) (pathway C in Figure 1B). Both at hippocampal and cortical synapses astrocytic Dserine rather than glycine, is the endogenous co-agonist of synaptic NMDA receptors (Papouin et al., 2012; Takata et al., 2011; Henneberger et al., 2010). By controlling the level of co-agonist site occupancy of postsynaptic NMDARs, astrocytic D-serine affects the level of activation of these receptors and thus activity-dependent long-term synaptic changes (Bains and Oliet, 2007). In particular, the additional burst of activation of postsynaptic NMDARs (about 25% more) induced by astrocyte D-serine release seems necessary for LTP induction (Henneberger et al., 2010). Moreover, in conditions of reduced synaptic coverage by astrocytes, such as during lactation in the hypothalamus, higher presynaptic activity is required to obtain LTP while the same level of activity that normally induces LTP results instead in LTD (Panatier et al., 2006). In such conditions, astrocyte-released D-serine is diluted in the larger extracellular space resulting in a reduced number of postsynaptic NMDARs recruited by synaptic activity, which ultimately translates into smaller postsynaptic Ca²⁺ increases. Therefore, experimental protocols that would be expected to cause LTP, elicit LTD instead. This is in agreement with the Bienenstock-Cooper-Munro (BCM) model for variation of the threshold

for LTP, which predicts that the relationship between synaptic activity and persistent changes in synaptic strength can vary according to the number of NMDARs available during synaptic activation (Abraham and Bear, 1996; Bienenstock et al., 1982). Effectively, by adjusting the D-serine occupancy of the NMDAR co-agonist-binding site, astrocytes can shift the relationship between activity and synaptic strength (Panatier et al., 2006).

Besides D-serine, experimental evidence hints that glutamate and ATP released from astrocytes could also directly bind postsynaptically-located receptors and accordingly, play a role in regulation of long-term synaptic plasticity. In the paraventricular nucleus of the hypothalamus for example, ATP released from astrocytes could directly target postsynaptic P₂X₇ receptors, promoting insertion of postsynaptic AMPARs which results in LTP of synaptic transmission (Gordon et al., 2005). Interestingly, ATP release is mediated by Ca²⁺ dynamics triggered in astrocytes by noradrenergic afferents which, in the hypothalamus, generally lack direct postsynaptic contacts (Sawyer and Clifton, 1980), thus hinting that signaling in this vital homeostatic circuit may require dynamic neuronglia interactions.

Glutamate released from astrocyte could also target extrasynaptically-located NR₂B-containing NMDA receptors at postsynaptic terminals, triggering slow inward currents (SICs) (Navarrete et al., 2012; Pirttimaki et al., 2011; Bardoni et al., 2010; Navarrete and Araque, 2008; D'Ascenzo et al., 2007; Fellin et al., 2004) mainly mediated by Ca²⁺ ions (Cull-Candy et al., 2001), whose depolarizing action could affect postsynaptic neuronal firing (Pirttimaki et al., 2011; D'Ascenzo et al., 2007). In the primary visual cortex, nucleus basalis-mediated cholinergic activation of astrocytes mediates an increase of SICs frequency which correlates with a long-lasting increase of firing activity in visual responses of V1 excitatory neurons (Chen et al., 2012). The ensuing modulations of firing activity of these neurons by astrocyte-mediated SICs might ultimately affect STDP at individual synapses controlling orientation-specific responses of V1 neurons to visual stimuli (Jia et al., 2010).

Modulation of synaptic transmission by Ca²⁺-dependent gliotransmission may not be limited to the very synapses that trigger Ca²⁺ activity in the astrocyte but it could also affect farther synaptic domains in a multimodal fashion (Kozlov et al., 2006), depending

both on the morphology of the sites of astrocyte-synapse reciprocal communication (Haber et al., 2006; Ventura and Harris, 1999) and the functional connectivity of the astrocytic network (Pannasch et al., 2011). High-frequency activity of a Schaffer collateral fiber can trigger the potentiation of synaptic transmission at the same fiber but heterosynaptic suppression of another, adjacent fiber, by inducing ATP release from an astrocyte interposed between the two fibers (Pascual et al., 2005; Zhang et al., 2003). In the somatosensory cortex in particular, astrocyte-mediated heterosynaptic suppression could modulate GABAergic inhibitory transmission (Benedetti et al., 2011) which plays a dominant role in the control of cortical neuronal excitability (Swadlow, 2002). Given that both experimental observations and theoretical arguments suggest that excitation and inhibition are globally balanced in cortical circuits (Haider et al., 2006; Shu et al., 2003; Troyer and Miller, 1997; Shadlen and Newsome, 1994), one may speculate that this mechanism could be involved in gating of signal transmission (Buzsáki, 2010). That is, by modulating inhibitory synaptic transmission, astrocytes could favor network excitation resulting in neuronal firing consistent with the transmission, i.e. gating 'on', of specific stimuli rather than others (Vogels and Abbott, 2009).

The latter idea could also bring to a possible role of astrocyte signaling in coherent function of neural networks underlying potential behavioral states (Engel et al., 2001). In cortical slices, for example, stimulation of a single astrocyte was reported to activate large portions of the astrocytic network and to result in an increase of synchronized neuronal depolarizations (Poskanzer and Yuste, 2011). This phenomenon was suggested to modulate the induction of cortical UP and DOWN states, possibly involved in determining the oscillatory activity observed in slow-wave sleep (Fellin et al., 2004; Poskanzer and Yuste, 2011; Halassa and Haydon, 2010) and is consistent with reports of sleep perturbations in mice lacking astrocytic gliotransmitter exocytosis (Fellin et al., 2012; Fellin et al., 2009; Halassa et al., 2009).

Conclusions

A large body of evidence has accumulated over the last years, suggesting an active role of astrocytes in many brain functions. Collectively these data have fuelled the concept that synapses could be tripartite rather than bipartite, since in addition to the pre- and post-synaptic terminals, the astrocyte could be an active element in synaptic transmission

(Haydon, 2001; Araque et al., 1999). While the tripartite synapse concept captures well the essence of astrocyte-regulated synapses, the inclusion of astrocytic signaling within our current knowledge of synaptic transmission could add more than just one level of complexity. Existing evidence suggests that astrocytes could produce not just tonic and diffuse modulatory influences on synapses but also engage in more focused, spatially precise and constrained communications with synaptic terminals (Bergersen et al., 2011; Santello and Volterra, 2009; Jourdain et al., 2007; Anderson and Swanson, 2000). This calls to rethink the definition of a functional synapse, to include the contribution from surrounding astrocytes. To conclude, the growing appreciation that astrocytes can regulate synaptic information at many levels, from activity of single synapses to network levels and behavioral states (Zorec et al., 2012; Halassa et al., 2009; Fellin et al., 2009) changes our understanding of brain communication and the role of glial cells in synaptic transmission. This resulting novel scenario offers an enticing platform for future theoretical investigations that we are just beginning to appreciate in its potential farreaching implications.

Figure Captions

Figure 1. The signaling network of astrocyte-synapse interactions. (A) A simplified scheme of the different signaling pathways between synaptic terminals and astrocytes for the case of excitatory synapses in the hippocampus (see text for a detailed description). Action potentials arriving at the presynaptic terminal trigger release of glutamate, which can spill over from the synaptic cleft. Perisynaptic astrocytes take up glutamate using their plasma membrane transporters (EAATs) while glutamate, by acting upon astrocytic metabotropic receptors (mGluRs), triggers Ca²⁺ signaling in the astrocyte. This signaling pathway includes production of IP₃ and causes an increase of cytosolic Ca²⁺ due to efflux of this ion from the endoplasmic reticulum (ER). At some synapses, such as in the dentate gyrus, the same Ca²⁺ signaling pathway could also be mediated by astrocytic purinergic P₂Y₁ receptors, likely activated by synaptically-released ATP (see text for details). Astrocytic Ca²⁺ excitability can in turn lead to exocytotic release of several neuroactive substances (or "gliotransmitters") such as glutamate (Glu), D-serine (D-ser) or ATP which can target specific receptors on pre- and post-synaptic terminals and differentially modulate synaptic transmission. Glutamate acting on presynaptic GluRs could enhance synaptic release, whereas ATP and its derivate adenosine (Adn) could depress it (red path) through presynaptic purinergic receptors (PRs). On the postsynaptic spines (depicted here by a standard RC circuit (Ermentrout and Terman, 2010), the ensuing effect of gliotransmitters could substantially modify postsynaptic currents by enhancing activation of NMDA receptors (D-serine) or by altering expressions of AMPA receptors therein. Astrocytes could also release TNFα by Ca²⁺-dependent activation of the matrix metalloprotease TNFα-converting enzyme (TACE), while extracellular TNFα could in turn regulate glutamate release from the astrocyte as well as postsynaptic AMPAR expression. Moreover astrocytic Ca²⁺ could also propagate across different regions of the same cell or to other neighboring astrocytes by intracellular IP₃ diffusion through gap junction channels (GJCs) or via extracellular ATP-dependent pathways, extending gliotransmission to some distal sites away from the considered synapse. For clarity both endocannabinoid-mediated Ca²⁺ signaling (Navarrete and Araque, 2008), retrograde activation of presynaptic glutamate receptors (Navarrete and Araque, 2010), regulation of postsynaptic NMDARs by presynaptic adenosine receptors (Deng et al., 2011) and the possibility for astrocyte-derived adenosine to enhance synaptic release (Panatier et al., 2011) are not included in this scheme. (**B**) Equivalent modeling scheme for astrocyte-synapse interactions. The astrocyte (ASTRO) constitutes a third active element of the tripartite synapse in addition to the presynaptic (PRE) and postsynaptic (POST) terminals. In its presence, the flow of input (IN) signals to the output (OUT) is no more unidirectional but presynaptically released neurotransmitter can affect astrocyte function through the interaction pathway A. In turn, the astrocyte can regulate both synaptic terminals via pathways B and C. In addition, the astrocyte could receive additional inputs from or send output to remote synapses in a heterosynaptic fashion (I/O).

Figure 2. Computational aspects of astrocytic Ca²⁺ signaling. (A) Scheme of IP₃mediated Ca²⁺-induced Ca²⁺ release in the astrocyte. Calcium and IP₃ signals are controlled by synaptic glutamate through metabotropic glutamate receptor- (mGluR-) PLCβ-mediated IP₃ production (see text for details). (**B**) IP₃ and Ca²⁺ signals can be envisioned to encode incoming synaptic activity through frequency and amplitude of their oscillations. Astrocytes could thus encode synaptic information either by the modulation of the amplitude (AM), the frequency (FM), or both (AFM) of their Ca²⁺ oscillations. (C) Simulated Ca²⁺ and IP₃ patterns in response to sample synaptic glutamate release (Glu) in a model astrocyte (De Pittà et al., 2009) reveals that IP₃ signals could be locked in the AFM-encoding independently of the encoding mode of the associated Ca²⁺ signals. This feature could allow the astrocyte to optimally integrate synaptic stimuli. (**D**, top) Simulated Ca²⁺ (black trace) and IP₃ (green trace) signals in the same astrocyte model as in (C), and associated rates of IP₃ production (prod.) and degradation (degr.) (middle panels, dashed black lines) in response to two consecutive synaptic glutamate release events (bottom panel, Glu). The analysis of the contributions of different enzymes to IP₃ signaling (solid colored traces; cyan: PLCβ; pink: PLCδ; orange: IP-5P; purple: IP₃-3K) reveals dynamical regulation by Ca²⁺ of different mechanisms of IP₃ production/degradation which could ultimately underlie dynamical regulation of astrocyte processing of synaptic stimuli. (E) Simulated propagation of Ca²⁺

waves in a heterogeneous linear chain composed of both FM (*red traces*) and AFM (*blue traces*) astrocytes reveals that encoding of synaptic activity (STIMULUS) could change according to cell location along the chain. Adapted from (Goldberg et al., 2010).

Figure 3. Linking gliotransmitter exocytosis to various Ca²⁺ encoding modes. (**A**) Calcium-dependent glutamate and ATP exocytosis from astrocytes are both brought forth by a vesicular compartment in the astrocyte competent for regulated exocytosis. The frequency of exocytotic events is directly controlled by the shape and frequency of Ca²⁺ oscillations. (**B**) Modeling concept for an "exocytosis event" from the astrocyte. Calcium (*top trace*) triggers exocytosis of glutamate or ATP every time it increases beyond a certain threshold concentration value (*red dashed line*). The overall release can then be approximated, under proper assumptions, by an exponentially-decaying pulse of extracellular concentration of glutamate or ATP (*bottom trace*). (**C**) Distinct Ca²⁺ encoding patterns could translate into distinct rates of gliotransmitter exocytosis events. The synaptic activity encoded by astrocytic Ca²⁺ signals is linked to the frequency of glutamate/ATP release from the astrocyte in a unique fashion. Adapted from (De Pittà et al., 2011).

Figure 4. Glutamate or ATP released from astrocytes regulates transitions between facilitation and depression of synaptic transmission. (**A**) Conceptual framework for the regulation of synaptic release probability at basal conditions by astrocytes. Astrocyte-released glutamate increases the basal synaptic release probability (U_0), whereas astrocyte-released ATP/Adn generally decreases it. (**B**) Changes in synaptic release probability due to astrocytic gliotransmitters can be detected by variations of paired-pulse plasticity quantified by paired-pulse ratio (PPR). Paired-pulse facilitation (*left, green traces*) of postsynaptic currents (PSCs) corresponds to PPR values above 1 (*right, green-shaded area*) whereas paired-pulse depression (*top*, magenta traces) are associated with PPR values below 1 (*right, magenta-shaded area*). (**C**) Raster plots of simulated PSC pairs for 100 different input spike trains with same statistics colored according to the paired-pulse ratio: *green* for facilitation, PPR > 1; *magenta* for depression, PPR < 1. For increasing rates of exocytosis of gliotransmitter from the

astrocyte, mimicked by increasing rates of Ca²⁺ crossing beyond the threshold for exocytosis (*top row*, *red dashed line*), synaptic plasticity could be progressively changed to its opposite depending on the type of gliotransmitter. Astrocytic glutamate could thus turn facilitating synapses into depressing (*middle row*) whereas astrocyte-derived ATP or adenosine could turn depressing synapses into facilitating (*bottom row*). Simulations are based on a model of astrocyte-regulation of synaptic release introduced in (De Pittà et al., 2011). 'Basal Synaptic Release Probability' in (**B**) refers to the probability of synaptic release at rest, that is when synaptic activity is assumed to be very low and the amount of neurotransmitter released upon arrival of an action potential to the presynaptic terminal is essentially independent of previous release events (De Pittà et al., 2011; Zucker and Regehr, 2002).

Figure 5. Short-term synaptic plasticity is physiologically set by the rate of gliotransmitter release from the astrocyte. (**A**) The rate of glutamate or ATP release from the astrocyte could differently affect basal synaptic release probability. In particular, a threshold frequency for the release of these gliotransmitters could exist (*blue vertical line*) beyond which a depressing synapse could turn into facilitating (*right*, *green area*) or vice versa, a facilitating synapse could become depressing (*left*, *magenta area*). Adapted from (De Pittà et al., 2011). (**B**) In basal conditions, synaptic release is due to sporadic neuronal network firing and the possible frequency of Ca²⁺ fluctuations beyond the threshold for exocytosis (*dashed red line*) in the astrocyte (*top trace*). In this fashion plastic changes in paired-pulse ratio could be inherently regulated by astrocytic gliotransmitters, as shown here for the case of an originally facilitating synapse under the effect of astrocytic glutamate exocytosis (20 trials with identical input statistics). Adapted from (Berry et al., 2011). The color code for the raster plot is the same as in Figure 4C.

Table 1. Transmitters targeting receptors have major effects on synaptic transmission through the signaling pathways A, B, C in Figure 1B based on *in situ* and *in vivo* studies. Reference to *in vitro* studies is included whenever the latter are missing. Legend: 1. Specimen. F: frog; H: human; M: mouse; R: rat. 2. Preparation. VT: in vitro/cultures; ST: in situ/slices; VV: in vivo. 3. Brain area or body area. BC: barrel cortex; CA1: Cornu Ammonis area 1; CER: cerebellum; COR: cortex, DH: dorsal horn; HIP: hippocampus; MLDG: molecular layer dentate gyrus; NAcc: nucleus accumbens; NMJ: neuromuscular **PVN**: paraventricular nucleus of the hypothalamus; junction; **Ret**: retina: **VBT**: ventrobasal thalamus: **V1**: primary visual cortex; **VC**: visual 4. Synaptically-released neurotransmitter. ACh: acetylcholine; ECB: endocannabinoids; **NE**: norepinephrine. **5**. Astrocytic targeted by receptors synaptically-released neurotransmitters (pathway A) and neuronal receptors targeted by gliotransmitters (pathways B, C). $\alpha AR (\alpha_1 AR)$: α - (α_1-) adrenergic receptors; CBR: cannabinoid receptors; **iGluR**: ionotropic glutamate receptors; **KAR**: kainate mAChR: muscarinic receptors; mGluR-I, mGluR-II/III: group I (II/III) metabotropic glutamate receptors. 6. Gliotransmitter released from astrocyte. 7. Cell targeted by gliotransmission, where targeted receptors and effects were reported. AC: amacrine cell; CN: cortical neuron; GC: granule cell; IN: interneuron; MF: muscle fiber; PF: parallel MNC: magnocellular neuroscretory **PY**: pyramidal neuron; MSN: medium spiny neurons; SGN: substantia gelatinosa neuron; RN: retinal neuron. V1N: V1 excitatory neuron; 8. Effects triggered by gliotransmission on pathways B or C in Figure 1B. (f)EPSP: (field) excitatory postsynaptic potential; mEPSC (mIPSC): miniature excitatory (inhibitory) postsynaptic current; t-LTP (t-LTD): spike-timing dependent long-term potentiation (depression); LTP: long-term potentiation; PTD: posttetanic depression; PTP: post-tetanic potentiation; SICs: slow inward (depolarizing) currents; **SOCs**: slow outward (hyperpolarizing) currents. Arrows denote increase (\(\frac{1}{2}\)) or decrease (1) and are followed by the associated signal, i.e. $\uparrow(\downarrow)$ EPSP (frequency)(amplitude)(slope): increase (decrease) in (frequency)(amplitude) (slope) of EPSPs. **fEPSP**, filed EPSP. **Other**: **b**: study on Bergmann glia cells; r: retrograde signaling; s: suggested by investigators; m: study on Müller glia cells; n.r.: when existence of a specific signaling pathway is observed but details are not reported; *: indirect evidence.

Table 2. Comparison of time scales for rising and decaying phase and full-width half-maximum (FWHM) duration of intracellular Ca^{2+} , and extracellular glutamate (Glu) and ATP changes in astrocytes and in neurons. Glutamate and ATP values refer to transient increases of their extracellular concentrations following release in a Ca^{2+} dependent fashion. Therefore they describe the time course of the *overall* glutamate and ATP released by an exocytotic burst rather than by a single exocytotic event which can be much faster and occur within the first ~50 ms from Ca^{2+} rise (see text). Indicative rise and decay time constants as well as FWHM values are reported in terms of min-max ranges. Fast calcium signals imaging in astrocyte in the somatosensory cortex reported by (Winship et al., 2007) are reported separately and dubbed by 'a'. The letter 'f' stands for values that were obtained by fitting of experimental data by a biexponential function such as $f(t) = C \cdot (\exp(-t/\tau_{decay}) - \exp(-t/\tau_{rise}))$ with C being a proper scaling factor. Asterisk '*' denotes values estimated by a model of astrocytic and synaptic release introduced in (De Pittà et al., 2011).

Signal	Origin	τ _{rise} [s]	τ_{decay} [s]	FWHM [s]	Essential Reference
Ca ²⁺	Astrocyte (soma)	$2-20^{\mathrm{f}}$	$3-25^{\mathrm{f}}$	5 – 160	(Wang et al., 2006; Hirase et al., 2004; Nimmerjahn et al., 2004)
	Astrocyte (soma) ^a	~0.5	~1.1	~2 – 4	(Winship et al., 2007)
	Neuron (soma)	$2-5\cdot10^{-3}$	0.1 – 0.4	~0.1 – 0.3	(Nimmerjahn et al., 2004; Waters et al., 2003; Svoboda et al., 1997)
	Astrocyte (process)	0.1 - 0.2	$0.2 - 4^{f}$	~0.5 – 4	(Di Castro et al., 2011; Panatier et al., 2011)
	Neuron (presynaptic bouton)	$0.5 - 5 \cdot 10^{-3}$	~0.1 – 2	0.1 – 1*	(Emptage et al., 2001; Regehr et al., 1994)
Glu	Astrocyte	0.2 - 0.5	0.5 – 1.5	1 – 6	(Santello et al., 2011; Marchaland et al., 2008; Domercq et al., 2006)
	Neuron (synapse)	$1 - 5 \cdot 10^{-4}$	0.01 – 0.1	0.01 - 0.1*	(Okubo et al., 2010; Herman and Jahr, 2007; Raghavachari and Lisman, 2004)
ATP	Astrocyte	0.1 - 0.5	2 – 3	2 – 20	(Pangršic et al., 2007; Li et al., 2008)
	Neuron (synapse)	$1 - 5 \cdot 10^{-4}$ *	0.2 – 1*	0.15 – 0.5	(Pankratov et al., 2007; Dundwiddie and Masino, 2001)
